Summary

Real-time elastography is a new ultrasonographic technology for measurement of tissue elasticity. Malignant lesions in the human breast, prostate, thyroid and lymph nodes show significantly reduced elasticity. The present study investigated the use of real-time elastography in the spleen of 22 dogs (8 benign and 6 malignant nodules, and 8 normal spleens) and results were compared to contrast-enhanced ultrasound findings. In summary, real-time elastography was neither able to differentiate benign from malignant splenic lesions, nor normal from diseased splenic tissue. No significant associations with contrast-enhanced ultrasound results were found. Real-time elastography, therefore, does not appear a useful tool for the differentiation of splenic nodules in the dog.

Keywords: spleen, dog, real-time elastography, contrast-enhanced ultrasound, ultrasound

Introduction

Neoplastic diseases occur with high incidence in the canine spleen, and differentiation between malignant and benign changes is crucial because it influences treatment and prognosis. B-mode ultrasound is a commonly used, noninvasive and cost-effective tool in veterinary medicine to examine the canine spleen. It is considered highly sensitive for the detection of focal or diffuse lesions but its specificity is low. Moreover, splenic fine-needle aspiration has been reported to yield a correct diagnosis in only 61.3% and 51.4% of affected dogs, respectively. Histologic examination is therefore often required (Ballegeer et al., 2005; Watson et al., 2011).

Contrast-enhanced ultrasound with second-generation contrast agents represents a relatively new ultrasonographic technology for the investigation of tissue perfusion dynamics. Previous studies in dogs showed that the differentiation between malignant and benign focal splenic lesions was improved. In general, moderate to severe hypoechogenicity of a splenic nodule in comparison to normal spleen appears to be strongly suggestive of malignancy in dogs (Ohlerth et al., 2008). Characteristic vessel patterns such as feeding vessels or aberrant, tortuous intratumoral vessels have also been identified in malignant but not in benign focal splenic lesions (Taeymans and Penninck, 2011). However, marked enhancement during the vascular phases may likewise occur in benign as well as in malignant lesions. Then, contrast-enhanced ultrasound appears to be of limited value and histology is needed (Ohlerth et al., 2008).

Real-time elastography is a new ultrasonographic technology for measurement of tissue elasticity integrated in a conventional ultrasound machine with conventional probes (Ophir et al., 1991). It may be used to assess tissue elasticity with a penetration depth up to approximately 4 cm. Images are generated by slight compression and decompression of tissue, which is manually induced by the investigator using an abdominal ultrasound probe. Tissue compression results in deformation within the tissue. Harder, stiffer tissue will be less deformed e.g. less elastic
than softer, more elastic tissue (Garra, 2011). Real-time elastography computes the so-called strain (compressibility property of materials) by determination of local displacements between two consecutive images. After processing the radiofrequency ultrasound data, the elastogram is simultaneously displayed with conventional B-mode images (Ophir et al., 1991). The stiffness of the lesion is displayed in different, freely selectable colors. In focal lesions of the human breast (Barr, 2012), prostate (Pozzi et al., 2012), thyroid (Wang et al., 2013) and lymph nodes (Teng et al., 2012), it has been shown that malignant nodules are significantly stiffer than surrounding normal tissue. So far, one report in veterinary medicine describes real-time elastography as a feasible and repeatable method for the evaluation of the elasticity of the normal equine tendons (Seiler, 2011).

The objectives of the present study were 1) to assess the feasibility of real-time elastography for the evaluation of the elasticity of the canine spleen, 2) to verify that benign focal splenic lesions would present higher elasticity than malignant nodules, and 3) elastographic appearance of splenic nodules was compared to contrast-enhanced ultrasound findings to investigate if real-time elastography would help to differentiate lesions with marked enhancement, which according to the literature, may likewise represent benign as well as malignant lesions.

Animals, Material and Methods

Patients

A prospective study was conducted in dogs with single focal splenic lesions diagnosed during routine abdominal ultrasonography at the Section of Diagnostic Imaging at the University of Zurich between May 2011 and April 2012. Twenty-two dogs were included in the study: 4 Labrador Retrievers, 2 Golden Retrievers, and one each of various breeds. Age ranged from 1 to 13 years (mean 8.8 years; SD 3.6 years), and body weight ranged from 2 to 43 kg (mean 24.64 kg; SD 10.7 kg). Nine dogs were male and 13 were female. Dogs were included in the study if real-time elastography was performed and diagnostic ultrasound-guided aspirates or histopathologic samples were taken within the same day during surgery or necropsy. Lesions had to be located in a depth of less than 4 cm. Healthy dogs with normal spleens or dogs presented for clinical signs unrelated to the spleen were included as a control group. Cytology or histology was not available in these animals. Owner consent was obtained. The study was approved by the Animal Ethics Council of the Canton of Zurich.

Ultrasonography

During the ultrasonographic examination, 16 dogs were awake and kept in lateral recumbency with manual restraint only. Six dogs were sedated/premedicated with Butorphanol (Morphanol, 0.2 mg/kg) plus Midazolam (Dormicum, 0.2 mg/kg) IV, Fentanyl (Sintenyi, 5 – 10 μg/kg) plus Midazolam (Dormicum, 0.25 mg/kg) IV, or Methadon (Methadon Streuli, 0.2 mg/kg) or Butorphanol (Morphalin, 0.2 mg/kg) plus Acepromazin (Prequilan, 10 μg/kg) IM. Two dogs underwent subsequent general anesthesia with Propofol (Propofol 1% MCT Fresenius) given IV to effect. All examinations were performed with the same ultrasound unit (iU22, Philips, Zurich, Schweiz). The area of examination was clipped and lubricated with gel. The following criteria were assessed in the spleen with B-mode: size of the lesion, echogenicity in comparison to the surrounding normal splenic tissue, heterogeneity and presence of cavernous areas. Splenic tissue was considered normal if the contours were smooth and regular, and the parenchyma appeared uniform, finely textured and more echogenic than the liver and the cortex of the left kidney.

For real-time elastography, a L12-5 MHz linear array transducer was used in combination with a real-time elastography module. Slight compression of the spleen was manually induced with the probe. The compression feedback bar displaying the amount of tissue deformation in the ultrasound image had to be of a green color indicating an adequate amount of pressure. Tissue deformation was considered fair if the compression feedback bar was seen in the lower third of the green bar, and good or excellent if it was in the middle third or in the upper third of the green bar, respectively. The selected color scheme displayed soft, high strain areas in red, whereas intermediate, average strain areas were coded with a green color and hard, no strain areas with a blue color. At least one cine clip of a minimum of 20 seconds was obtained.

Contrast-enhanced ultrasound was performed subsequently to real-time elastography. A 3 – 9 MHz linear probe or a 2 – 5 MHz broadband curvilinear probe and pulse inversion harmonic imaging were used with standardized machine presets. While the probe remained in the same position, the contrast medium (Sonovue, 0.03 ml/kg) was administered IV through the cephalic vein as a rapid bolus followed by a rapid bolus of 5 ml saline. With the onset of injection, images were acquired for approximately 180 seconds and stored as dicom-files with the extended loop function of the ultrasound machine.

Image analysis

Elastography: Two authors (DA, SO) evaluated the images together. The 5-point scoring system described for human breast lesions (Zhi et al., 2010) was modified and applied. A score of 1 was defined as normal and even strain (green colour) in the lesion, equal to the surrounding tissue, respectively. A score of 2 represented normal strain in ≥75% of the lesion with some areas of less strain in the lesion (mosaic pattern, green and little blue) and normal strain in in the surrounding tissue. A score
of 3 described a heavily mixed pattern of less, normal or increased strain in the lesion, but normal strain in the surrounding area. A score of 4 represented largely absent strain in the lesion (blue) but normal strain in the surrounding tissue (green). A score of 5 indicated no strain in the lesion and surrounding tissue. A score of 1 to 3 was considered benign whereas a score of 4 or 5 was categorized as malignant.

The semiquantitative strain ratio was also applied in the present study. Two regions of interest, drawn as large as possible, were manually selected in every image in the lesion and the adjacent normal spleen, respectively. Both regions of interest were drawn at a similar tissue depth avoiding inclusion of larger vessels or cavitary areas. With dedicated software (QLab Version 8.1, Philips Ultrasound, Bothell, WA, USA) a ratio was calculated between the average strain of normal tissue and the lesion. For both, the elasticity score and the strain ratio, a minimum of 3 image sequences with ≥3 consecutive images of adequate quality were analyzed to calculate a mean.

Contrast harmonic imaging: The enhancement pattern (homogeneous, heterogeneous), presence of cavernous areas (yes/no), ring enhancement (yes/no), presence of feeding vessels during the early or late vascular phase (yes/no), lesion enhancement compared to normal spleen (hypo-, iso-, or hyperechoic) during the early, peak or late vascular phase were evaluated. Hypoechogenicity was subclassified as mild (marked enhancement of lesion with marginal hypoechogenicity in comparison to normal spleen), moderate (little enhancement of lesion) or extensive (no enhancement).

Statistical analysis

Because groups were small, nonparametric statistical tests were used. To assess the association of the elasticity score and the strain ratio with the continuous variables body weight and age Spearman correlation coefficients were calculated; for the categorical variables sex and anesthesia, the Mann-Whitney-U test was used. The Mann-Whitney-U test was also used a) to assess the association between mean elasticity score and strain ratio of lesions with malignancy, b) to compare mean elasticity score and strain ratio between normal spleen surrounding benign and malignant

lesions, and normal spleens of control animals, and, c) to assess the associations between mean elasticity score and strain ratio of lesions with the degree of hypoechogenicity during the early, peak and late vascular phase. The Wilcoxon-signed-rank test was used to compare mean elasticity score of lesions and normal spleen surrounding the nodules. All statistical analyses were performed with commercially available software (IBM SPSS Statistics Version 19, Zurich, Switzerland). Level of significance was p < 0.05.

Results

No significant association was found between the continuous variables age and body weight and the elasticity variables, respectively. There was neither a significant difference between male and female dogs, nor sedated and non-sedated animals.

In all diseased spleens, ultrasound-guided fine needle aspirates (11) or histology (3) was available. Eight lesions were considered benign, 6 nodules were malignant (Tab. 1).

Three lesions were hypoechoic and 11 nodules were of mixed echogenicity. Cavitary areas were diagnosed in 7 lesions, independent of their cytological diagnosis (i.e., benign or malignant). Quality of elastographic images was good to excellent in 19 (86.3%) cases, the remaining 3 cases classified as fair. Mean elasticity score did not significantly differ between benign and malignant lesions (p = 0.3), between normal spleen tissue surrounding benign or malignant nodules and healthy spleens of the control group (p = 0.6), and between all lesions and normal surrounding spleen tissue (p = 0.6) (Fig. 1). Likewise, mean strain ratio did not significantly differ between benign and malignant lesions (p = 0.9).

Contrast-enhanced ultrasound was performed in 10 (5 benign, 5 malignant) of the 14 nodules. The overall quality of the contrast harmonic imaging was good to excellent in all but one examination with fair quality. The pattern of enhancement was heterogeneous in 5 lesions. Ring enhancement was found in 2 nodules. Tortuous feeding vessels during the early and late phase were identified in 1 benign and 3 malignant lesions. Degree of enhancement of the lesions in comparison to normal spleen is shown in Table 1. If lesions were categorized in two groups for every vascular phase (extensive to moderate hypoechogenicity versus mild hypoechogenicity to hyperechogenicity), mean elasticity score and strain ratio did not significantly differ between the two groups for the early, peak or late vascular phase (p = 0.14—0.9).

Discussion

In various human organs, malignancies were shown to be significantly stiffer than benign lesions or surrounding normal tissue (Garra, 2011). Because of the limitations of B-mode, real-time elastography could represent an easy accomplishable and non-invasive tool to differentiate benign from malignant splenic lesions in the dog, in particular if combined with contrast-enhanced ultrasound. In the present study, real-time elastography appeared feasible but no additional diagnostic value was found. Mean elasticity scores and strain ratios were very similar for all canine splenic tissues and ranged between 3.4 and 3.8 and 0.9 and 1.32, respectively. Compared to the human classification, the present elasticity scores indicate moderate stiffness in all splenic tissues, independent of the presence and type of disease. The calculated mean strain ratio was around 1, indicating similar moderate stiffness of normal, benign and malignant splenic tissue. For comparison, mean strain ratios in benign and malignant human breast lesions were 1.83 and 8.42, respectively, with a cutoff point of 3.05 and an accuracy of 91.4% (Zhi et
The implication of the extracellular matrix are lacking. Al-
though real-time elastography was easy to perform in the
present study, animal-specific factors such as increased
abdominal wall tension may have played a role decreas-
ing the overall elasticity of the spleen and/or nodules. A
limitation of the present study may represent the use of
real-time elastography as an elastographic method since
it only allows subjective and semiquantitative assessment.
In human medicine, newer techniques allowing a quan-
titative approach (measurements in Pascal) are more
sensitive and reliable (Nightingale, 2011). The above-
mentioned factors and the small number of examined
animals may have contributed to the moderate and simi-
lar elasticity measurements in both, normal spleen tissue
as well as benign or malignant lesions.

In conclusion, real-time elastography was not found a
useful tool for the differentiation of splenic nodules in
the dog. However, newer techniques allowing a quantita-
tive approach to measure tissue stiffness should be inves-
tigated in a larger cohort of dogs in the future. Studies
on the microenvironment of splenic tumors, in particular
the behavior of tumor stroma in the spleen, are pending.
